```
In [3]: # take two moving averages and apply the sign-function, adjust by volatility
def f(price, fast=32, slow=96, volatility=32):
    s = price.ewm(com=slow, min_periods=300).mean()
    f = price.ewm(com=fast, min_periods=300).mean()
    std = price.pct_change().ewm(com=volatility, min_periods=300).std()
    return np.sign(f-s)/std
```

```
In [6]: form = EasyForm("Configuration")
    form.addTextField("fast")
    form.addTextField("slow")
    form.addTextField("volatility")
    form.addButton("Go!", tag="run")
    form
```

```
portfolio = Portfolio(prices=prices, position=prices.apply(f, fast=int(form["fast"] orange analysis(portfolio.nav())
```

- This is a **univariate** trading system, we map the (real) price of an asset to its (cash)position
- Only 3 free parameters used here.
- Only 4 lines of code
- Scaling the bet-size by volatility has improved the situation.

Results do not look terrible but...

No concept of risk integrated

Often hedge funds outsource the risk management to some board or committee and develop machinery for more systematic **parameter-hacking**.
